A SIMPLE INSTANT DIET FOR REARING ARCTIIDAE AND OTHER MOTHS

RAINER BERGOMAZ AND MICHAEL BOPP1
Universität Regensburg, Zoologie, NWFA 56, Universitätstraße 31, D-93040 Regensburg, Federal Republic of Germany

ABSTRACT. A bean-based semiartificial diet was developed empirically for rearing species of Rhodagastria and Creatomotor (Arctiidae). Insects for which were unavailable or unknown. It was also used successfully for Heterotera in 27 genera of five families, and it is likely valuable for rearing additional species of moths. Preparation of the diet is simple even in the field, and its components are inexpensive.

There are many practical reasons for attempting to rear insects on artificial diets, in particular to provide food independent of place or season. Numerous diet recipes have been published (Vanderzant 1974, Singh 1977, Singh & Moore 1985), most of which are based on either wheatgerm, wheatgerm and casein or beans. Their diversity arises mainly from their various sources of vitamins, proteins, carbohydrates, fatty acids, and preservatives. Most published diets for Lepidoptera have been tested with only one or a few closely related species, and rearing success can seldom be standardized to permit fully objective comparisons. The suitability of a certain diet for any given but unrelated species is thus not predictable.

Faced with the need to breed Rhodagastria and Creatomotor (Arctiidae), we considered artificial diets because the natural foodplants were either unknown or not continuously available. We also wanted a simple medium for use under field conditions in the tropics. To these ends, we modified recipes from the literature in a largely empirical fashion until we ended with an instant diet, which is cheap and easily prepared even during field work in the tropics. This simple diet also

appeared well suited to rearing other arctids and a variety of species of other heterocera families.

### Materials and Methods

**Diets**

Diets initially tested were based on wheatgerm, and were similar to those described by Vanderzant (1967) and Bel and Joachim (1976). These were modified by using frozen, tinned, or dried beans (Vicia faba, *Soja hispida*), testing mixtures of beans and wheatgerm in different proportions, and adding protein, salts, and vitamins as well as leaf-powders in varying amounts. Eventually, we omitted several standard ingredients of artificial diets to create a simpler recipe. The diet we found best (Table 1) is prepared by parboiling water, and adding the agar while stirring. Other ingredients are then mixed thoroughly (preferably with an electric hand mixer) with the gelling agar. Flat plastic dishes are filled with this gel to a depth of 4 cm. Cooling and drying is allowed for up to 12 h at room temperature before storage in a refrigerator. With refrigeration, this diet can be stored for at least five weeks, in a field, smaller amounts of diet were prepared to last for three to five days.

After obtaining good rearing results with this diet, we modified it slightly to produce an instant diet which could be prepared more easily, particularly during field work in the tropics. The only departure from the original recipe is that 0.05% p-formaldehyde (solid) was sub-
stitted for formaldehyde solution; also, in the field, germ oil and α-tocopherol were omitted. Agar and a mixture of all other solid in-
gredients were put separately into two plastic containers, which allows for storage and transport (mailing) without refrigeration. When the diet was required, it was prepared by merely mixing agar with boiling water and adding the mixture (and oil) while stirring thoroughly. In practice, we use a 10 ml plastic container to measure 1 part of agar, 6 parts of the mixture, and 20 parts of water (or multiples thereof if more diet is required). However, these proportions work only if the beans are ground finely (as coffee for filtering), and high gel-strength agar (SERVA, Heidelberg, New York) is used; otherwise, different weight-to-volume relationships have to be determined.

Insects

_Rhodogastra phaedra_ (Weymer) from Kenya (East Africa) and _Creatonotos transiens_ (Walker) from Sumatra, Indonesia, were exten-
sively investigated. Stocks originated from inseminated females sent to our laboratory. The foodplants of _Rhodogastra phaedra_ are unknown, and the few known for other _Rhodogastra_ are not available to us. _Creatonotos transiens_ is a polyphagous species which we had previ-
ously reared successfully on European substitute foodplants such as _Tanacetum officinale_ L.

The suitability of the simplest recipe (the instant diet) was tested with several European and tropical Lepidoptera (Table 2) to which we had unexpected access.

In routine cultures, as many as 50 neonate larvae were put into a clear plastic Petri dish (94 mm × 16 mm) containing a piece of diet (about 6 × 6 × 3 mm). Moistened filter paper was sometimes added. Later instars were kept in groups of 10 to 50 in plastic containers (200 × 200 × 95 mm), and given larger (but always 5 mm thick) pieces of diet. Every third day, larvae were transferred to a clean container with fresh diet. For quantitative rearing data, larvae were sometimes kept singly in Petri dishes.

We usually assessed the success of a diet by comparing the visual appearance of adults with field-caught specimens, and by checking the fecundity of females and the fertility of their eggs. In some cultures we also compared diets by weighing paper, counting eggs, and meas-
uring rates of development. For reasons given below, however, we re-
port only on our final results, and omit the presentation of detailed data.

**RESULTS**

The diets of Vanderzant (1967) and Bell and Joachim (1976) were only moderately successful with _Rhodogastra_ and _Creatonotos_. Better
success was achieved by using beans instead of wheatgerm, while substituting casein by albumin and/or eggs as a protein source did not have as obvious effect. Using Phaseolus beans as a base, we stepwise left out casein, Wesson's salt (compare Singh 1977) and/or vitamin solutions without reduced rearing success. Later, sucrose, choline chloride, and inositol were found to be unnecessary additions. The resulting best recipe from our trial is given in Table 1.

With Crematogaster in particular, we noted a dramatic group effect: larvae kept individually resulted in pupae which were up to 90% light than those of larvae kept in groups of 15-20. Thus, optimal rearing does not always depend on diet composition alone; indeed, other breeding conditions can be of overriding importance.

Notable general observations were, briefly: 1. White beans (Phaseolus compressus var. alb us) appeared to be a better base for artificial diet than horse-beans (Vicia faba); this finding supports the experience of El-Guindy et al. (1978). 2. Soaking beans (previously done by most authors, such as Stover & Hale 1965) proved unnecessary; pulverizing the seeds greatly simplifies preparation. 3. The use of methyl-p-hydroxybenzoate and sorbic acid enables extended storage of diet without refrigeration, and combats insect pathogens. Their concentration should nevertheless be kept as low as possible, and they can be omitted if the culture is healthy, and the diet is replaced frequently. 4. The quantitative composition of diet ingredients, particularly of water, appears less important than we originally judged from the literature.

Larvae of 38 species of moths, belonging to 27 genera of five families (Table 2) accepted our simple diet and developed with no unexpected mortality to adults that did not differ noticeably in size, color, and other characteristics from field-caught material. Females invariably proved fecund and eggs fertile. Rearing success from newly hatched larvae to adults was 50-100% in all species. Most species were reared for at least four generations (C. transiens for 20) without exhibiting apparent changes. However, larvae of several species, including Eu- chromia amoenia (Mischler) (Chenichidae), Antherea pernyi (Buerin- Meneville (Saturnidae), and all Rhopalocera, refused the diet. When checking the suitability of the simple diet with the species listed above, we experienced the following: 1. Preservatives may function as antifeedants; in some species we observed refusal if the concentration of methyl-p-hydroxybenzoate was higher than 0.1%. Hirai (1976) ob- tained similar results, and also reported noxious effects of sorbic acid. 2. When nonbacterial pathogens affected our cultures, we cured the larvae by adding 0.15% Fumigil B (Abbott Laboratories), a pharmaceutial marketed by CEVA, Paris, to treat honeybees for Nosema infection. 3. Using diets can cause a delay of two to three days before
newly hatched larvae begin feeding. 4. Diet is best accepted by neonate larvae, and it is often difficult or impossible to switch from foodplant to diet. 5. Addition of leaf powder to the diet (such as *Tetranychus indicus* for *A. gamma*) caused some neonate larvae to start feeding earlier than on diet lacking plant material, but always increased the
mortality of the larvae, and greatly prolonged development. 6. Color might be a cue in food detection and acceptance. Larvae of Autographa in a choice experiment preferred diet colored green by chromoxide (compare McGinnis & Kasting 1964). However, this did not result in better rearing success.

**Discussion**

We succeeded in our primary objective of rearing certain tropical moths whose foodplants are unknown or unavailable, and we found a diet suited to a wide spectrum of species. The diet we report not only enabled us to discover the features of previously unknown larvae, so as to facilitate search for their natural foodplants, but also to obtain adults for breeding and experimental studies.

Existing reports of rearing arctiids on artificial diets include those of Göttel and Philogene (1978) for Pyrrharctia isabella (J. E. Smith), Vail et al. (1967) for Ectemnene area (Drury), Singh (1977) for Hypaethria sp., Conner et al. (1981) for Uetheesa auritis, Bathon (1977) for Spodosoma maculata Stoll., and Moreau (1965) for Arctia caja L. Most of these diets are wheat-based. In contrast, our experience with Arctiidae showed that bean-based diets yield superior results. Apparently, beans have higher nutritive value for lepidopterous larvae than wheat-germ. Bean-based diets may also be easier to prepare, and are less expensive. Solts, vitamins, certain proteins, and other ingredients used by other authors can be omitted from bean-based diets, reducing costs significantly (1 kg of our instant diet costs ca. 7 Deutsch-Marks). In broad comparisons among reports, it must nevertheless be understood that significant differences occur in the quantitative and qualitative composition of nutrients between different species or strains of beans (Schlieper 1982).

Our medium turned out to be similar to the one described for noc-tuids by Shrewsby and Hale (1965). We have not compared our results with those of others because not only do the recipes differ, but also the species and rearing conditions — variables often as important as diet composition. Furthermore, due to the lack of natural foodplants for most species, we could not compare cultures on plants with those on diets.

We cannot explain why our diet proved successful for the variety of species tested. Though our results are certainly open to further refinement, we here report our findings as they stand now, and briefly discuss our experience because our instant diet is suited to a variety of unrelated species with different foodplant requirements. Also, in contrast to many other diets, it is easy to prepare, and inexpensive, and thus may help other workers, amateur and professional. Even if it
should not prove optimal for mass rearing of a given species, our diet may facilitate culturing of species not otherwise culturable, especially in the field.

ACKNOWLEDGMENTS

This study was supported by the Deutsche Forschungsgemeinschaft (SF48/96). We thank M. Bannow for laboratory assistance, A. Egeliard for partly providing rearing fa-
cilities, and A. Watson for identification of several species. We are also indebted to D. Schneider, to P. M. Breklein and, and, especially, to A. W. R. McCrack for valuable com-
ments on the manuscript. Suggestions by an anonymous reviewer helped to streamline the manuscript, and are acknowledged with thanks.
